Wooldridge Chp. Z - The Simple Regression Model

most of econometrics deals with relating two random variables y and x that represent some population.

usually, we are interested in "explaining y in terms of x"

We confront (at least) 3 issues in this process:

- 1) since there is never an exact relationship between two variables, how do we allow for other factors to affect y?
- 2 what is the functional relationship between y and x? } y= f(x)?
- 3) How can we be sure we are capturing a ceteris paribus relationship between y and x?

We start by writing down an equestion relating y to X as follows:

This equation is assumed to hold for the population of interest. It is called the Simple Regression Model.

In this model:

Y = explained variable (the variable we are interest in explaining)

X = explanatory variable (the variable we believe affects y)

(represents other factors affecting y)

The simple Regression Model addresses the issue of the functional relationship between y and X. It the other "
Anators in u are held fixed, so that the change in U
is zero, who then X has a linear effection on y.

Dy= BAX, if ALEO

The change in y is just the change in X multiplied by 12.

We call By the slope parameter; it is of primary interest in econometrics

The parameter B is the constant term or the twercept parameter.

Ex: 2.1 Vooldridge pp. 24

Suppose Soybean yield is determined by the model

yield = Po + P, Pertilizer + U

Then

y= yield

X = fertitizer

U may contain factors such as land quality, raturall,

The coefficient B, measures the effect of

fertilizer on soybean yield, helding all else constant

Ayield = B. A. Kertilizer

Ex: 2.2 Wage equation

A model that relates on individual's educations
to wage:

Wage = B + B, educ + U

If wage is measured in dollars per hour and educe is measured in years of education, then B, measures the change in hourly wage & given another year of education.

The linearity of

y = Bo + B, X + U

implies that a one-unit change in x has the same effect on y, regardless of the value of y.

Sometimes, his is unrealistic. For example, in the wage-education example we might believe that there is an increasing relationship, such that an additional year of education increases wages by more than the previous year of education does. We will allow for effects like this later.

Another important question is are we able draw ceteris paribus conclusions about how x affects y?

We have seen that B, does measure how & affects y, holding all other factors constant (in u).

Unfortunately this not the end of the causality issue. We will deal with this later. Basically though, correlation is not the same as causality. If for example, there is a third factor in il that causes both y and x then we can have problems.

EX: In the wage equation we might have a factor called "natural ability" in U. The econometrician will never observe this variousle, but it clearly relates to both y and X.

for now, we will make an assumption about U. As long as an intercept term Bo is included in the equation, nothing is lost by assuming

Note: if E(u) to but we include Bo the mean of a will get "sucked" into Bo

[fechnical standards]

term 3k

P code: nonzero_mean.r [Simulation to show the]

one additional (crucial) assumption regarding how u and x are related. A natural measure of the association between two variables is the correlation coefficient.

If x and u are uncorrelated, then they are not linearly related. Assuming that x and u are uncorrelated gyes a long way to defining how u and x should be unrelated to $y = \beta_0 + \beta_1 x + U$

But unfortunately, it is not enough. It is possible for u to be uncorrected with x but correlated with functions of x (such as x^2).

A stronger (better) assumption involves the conditional expectation of a given X. Namely

$$E(u|x) = E(u)$$
 our old friend the conditional distributions.

This says that the average value of the unobservables

15 the same across all the population determined called mean

by X, and that the common overage is just the independence assumption of average of the marginal distribution of U.

I.E. we can't learn anything about the average value of U. Knowing X. Here (in this situation) this is degirable.

Combining this with our earlier assumption about

E(u) (namely that E(u)=0) we have that

E(u|x) = 0

This is called the Zero conditional mean assumption

EX: Assume that U is the same as "innate ability". This assumption requires that the average level of ability is the same regardless of the years of education.

Note: Probably too strong an assumption as more able "people are more likely to be more educated

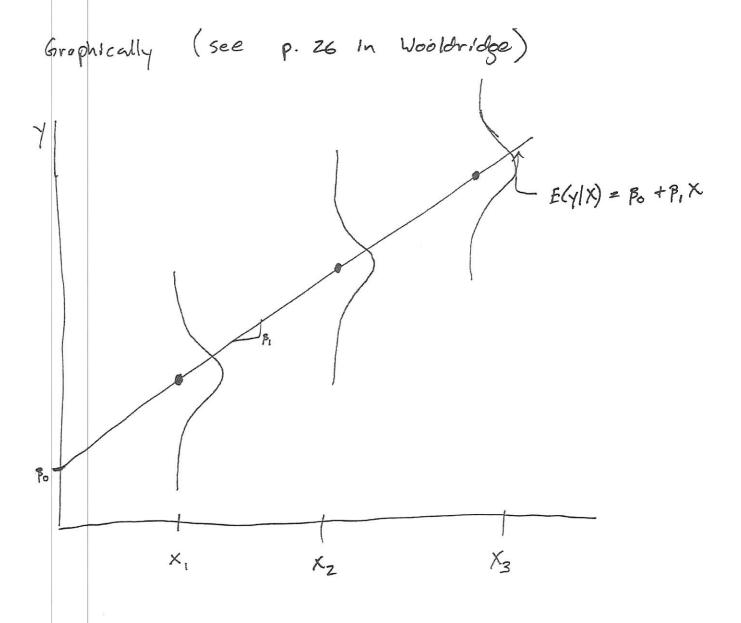

In the fertilizer example, if fertilizer amounts are chosen independently of other features of pleas then the assumption will hold. conditional mean more fartilizer is given to higher-quality plots of land then the expected value of U changes with the level of for tilizer. And the zero corelational mean assumption will not hold.

the expected value of (given X)

Y = β_0 + β_1 X + U

Says that a one-unit charge in X changes The expected value of y by B,

NB: $E(y|x) = P_0 + P_1 X$ tells now the average value of y changes with X.

Ordinary Least Squares Estimates

Q: How to get estimates for population parameters BO, B,?

A: Define un extimestor and use a sample of data!

Let {(xi, yi): i=1,..., n} denote a random sample of size

n from the population. These are drown from

the population

So for every i = 1,..., n we can write

Y; = Bo + B, X; + U;

Here U; is the error term for the jth observation because it contains all factors affecting Y; other than X;.

EX:

Y: = annual savings

X: = annual income

Ui = all other factors offertry household i's annual sartys other than X;

We assume that were u is uncorrelated with X

$$E(u) = 0$$

$$Cov(X, U) = E(XU) = 0$$

which can be written us

$$E(y-\beta_0-\beta_1X)=0$$
and
$$E(X(y-\beta_0-\beta_1X))=0$$

as sample of data we will choose

estimates β and β to some the sample

 $\frac{1}{n}\sum_{i}(y_{i}-\hat{\beta}_{o}-\hat{\beta}_{i}X_{i})=0$ $\frac{1}{n}\sum_{i}(y_{i}-\hat{\beta}_{o}-\hat{\beta}_{i}X_{i})=0$

Equation (*) can be re written as

了 = po + px

Where
$$\overline{y} = \frac{1}{n} \sum_{i=1}^{n} y_i$$
 and $\overline{x} = \frac{1}{n} \sum_{i=1}^{n} x_i$.

Then we can write \$ in terms of \$, 7, and X

Therefore, once we have the slope estimate β_1 , it is simple to get β_0 given γ and X

Dropping the In (does not affect the solution) and plugging

角= ダー 寛文 truto equation (***) y'elds

$$\sum_{i=1}^{n} x_{i} \left[Y_{i} - (\overline{y} - \overline{\beta} \overline{x}) - \overline{\beta}_{i} x_{i} \right] = 0$$

Which we can rearrange as

$$\sum_{i=1}^{n} \chi_i(y_i - \overline{y}) = \widehat{\beta}_i \sum_{i=1}^{n} \chi_i(y_i - \overline{x})$$

Using properties of summatton operators (see Appendix +)

$$\sum_{i=1}^{N} X_i \left(X_i - \overline{X} \right) = \sum_{j=1}^{N_j} \left(X_i - \overline{X} \right)^{Z}$$

and

$$\sum_{i=1}^{N} x_i (y_i - \overline{y}) = \sum_{i=1}^{N} (x_i - \overline{x})(y_i - \overline{y})$$

Then as long as
$$\sum_{i=1}^{n} (x_i - \overline{x})^2 > 0$$

$$\hat{\beta}_{i} = \frac{\sum_{i=1}^{n} (x_{i} - \overline{x})(y_{i} - \overline{y})}{\sum_{i=1}^{n} (x_{i} - \overline{x})^{2}}$$

This is simply the sample covariance of X and y divided by the sample variance of X
